COMPLETE SPECIFICATION

METHOD FOR DETERMINING PHYSICAL PROPERTIES

I/WE, THE BRITISH PETROLEUM COMPANY p.l.c.,
 Britannic House, Moor Lane, London EC2Y 9BU,
 ENGLAND, a British company,

hereby declare the invention, for which ~~X~~/We pray that a
 patent may be granted to ~~X~~/us, and the method by which it
 is to be performed, to be particularly described in and by
 the following statement

(followed by Page 1a)

METHOD FOR DETERMINING PHYSICAL PROPERTIES

This invention relates to a method for non-intrusively determining the physical properties of material in a mill during size reduction operations (comminution).

5 Comminution of solid materials, particularly minerals, is a frequently performed operation. For instance, some mineral ores are crushed and ground prior to extraction of the metal, pigments before addition to paints, and coal is similarly treated prior to combustion in large scale industrial furnaces. Equipment used during comminution is generally classified in three categories,
10 coarse mills such as jaw crushers, intermediate mills such as disc crushers and hammer mills, and fine mills such as roller mills, ball mills and rod mills.

Crushing and grinding are energy intensive processes. It has been estimated that they consume about 5% of the world's energy
15 output. In minerals processing, comminution is by far the largest operating cost. For example, in a survey of a number of Canadian copper concentrators, it was found that the average power consumption in KWh/tonne was 2.2 for crushing, 11.6 for grinding and 2.6 for flotation.

20 Commercial mills are usually indirectly controlled by sampling the ground material and measuring the slurry density or the viscosity off-line. This approach is unsatisfactory because the plant is controlled by out of date information.

For batch milling a direct, real-time measure of the particle
25 size distribution is desirable for optimum grinding.

It would be advantageous to provide this information on-line and in real time.

Sound is generated during comminution. This is usually considered to be an undesirable attribute of these processes.

5 We have now discovered that the frequency distribution of mill sound (acoustic frequency distribution) can be related to the properties of the material being milled and thus an apparent disadvantage can be turned to a positive benefit.

Thus, according to the present invention there is provided a
10 non-intrusive method for the determination of the value of a physical property of the material within a mill during the comminution of solid material within the mill which method comprises the steps of:

- 15 (a) detecting the acoustic frequency distribution of milling by means of a sound transducer, e.g. a microphone, the output from which is an analogue electrical signal, the intensity of which is proportional to the intensity of sound received by the transducer in the audio frequency range,
- (b) converting the analogue signal to a digital signal,
- 20 (c) passing the digital signal through a digital band-pass filter to select at least two frequency bands,
- (d) averaging the power in each band for a specified period of time, and
- 25 (e) analysing the acoustic power in the bands by means of a multivariate statistical technique to obtain the value of the property.

If necessary, the analogue electrical signal can be amplified and/or passed through a band-pass filter to remove frequencies above, say, 10 KHz to prevent aliasing, and below, say, 50 Hz to
30 remove spurious low frequency signals.

The digital band pass filter is preferably capable of selecting from two to twenty four desired frequency bands.

The properties which may be determined include those variables which fully characterise the material in a mill, namely, the
35 particle size distribution of the solid particles and when wet.

milling is employed, the pulp density (solid:liquid ratio) and the pulp volume (volume of solid and liquid). Other parameters of interest may be calculated from these.

Suitable multivariate statistical techniques are the methods of principal components analysis (PC) and partial least squares (PLS).

PC analysis is a numerical technique which allows multivariate data to be displayed in two dimensions for ease of interpretation. The PC's are vectors which are linear combinations of the original features and take the form:-

$$Y_j = A_{1j}X_1 + A_{2j}X_2 + \dots + A_{nj}X_n$$

where Y_j - jth principal component

X_n - feature

A_{nj} - coefficient

The PC's are all orthogonal and equal in number to the measured features. The coefficients of the vectors are calculated so that most of the variance in the data is expressed in the first few PC's whilst the relative magnitude of the coefficient reflects the discriminatory power of the original features. By transforming the data using equations of the above type the data may be plotted in a low dimensional form.

PLS analysis allows the relationship between sets of data (which are related or where it is expected that a relationship exists) to be empirically modelled. Two 'training sets' of data (in this case particle size distribution and AE (Acoustic Emission) frequency distribution) are used to generate the model. Having developed the model, validation is carried out. 'Test sets' of data, acquired under the same conditions but not used to build the model, are then input. Where actual values are known, the errors between these and the values generated are used to validate the accuracy of the model's predictions. If one set is unknown PLS is able to predict values from knowledge of the other, using the model.

For more details of the statistical methods which may be used, see for example the textbooks; "MULTIVARIATE ANALYSIS," Wold, H., Academic Press, New York, 1988, Krishnaiiah, P.R. (Ed.) and Sharaf, M.A., Illman, D.L and Kowalski, B.R., "CHEMOMETRICS", John Wiley and Sons Inc, New York, 1988. (Elving, P.J., Winefordener, J.D, and Kolthoff, I.M., eds)

The method is applicable to any type of milling machine including batch machines and continuous machines where mill efficiency is influenced by the amount and particle size distribution of the feed material. It is particularly suitable for use with ball mills.

It provides means for determining on-line and non-invasively particle size distributions, pulp densities and pulp volumes in near "real time".

The invention is illustrated with reference to Figures 1 to 16 of the accompanying drawings and the following Examples.

Figure 1 is a schematic diagram of apparatus for use in the method according to the present invention.

Figures 2 to 16 are diagrams showing respectively

- 20 2 - the change in particle size distribution during experiment 6.

- 14 - particle size change during continuous milling
- 15 - specific gravity change during continuous milling
- 5 16 - selected acoustic spectra changes during continuous milling

With reference to Figure 1, sharp sand was ground in a batch British Rema 0.61 m diameter x 0.92 m length ball mill 1 driven by an electric motor 2. The grinding medium was 16 mm diameter steel balls, filling (including voids) about 40% of the mill volume.

The sound intensity of grinding was picked up by a flat frequency response audio-microphone 3. This had a Bruel and Kjaer, Type 4165 cartridge and a Type UAC308 dehumidifier and was mounted in a fixed position close to the mill. It had a flat (± 1 dB) frequency response up to 10 KHz.

Electrical signals from the microphone were amplified using a Rhomicon Instruments MAPS 1 preamplifier 4.

The amplified signals were then analysed by a third octave analyser 6 (Data Beta, DEOTO-10). This comprises an analogue-to-digital converter 7 front-ended with a 12.5 KHz low pass anti-aliasing filter 5, a digital band-pass filter 8, a central processing unit (CPU) 9 and an RS-232 serial line interface 10. The band-pass filter uses a series of digital filters to divide the region 50 Hz to 10KHz into 24 bands. The centre frequencies of these bands are listed in Table 1. The analyser averages the power in each of these bands for a specified period. In all cases 10 seconds averaging times were used.

The system is controlled by an IBM PC-AT computer 11 linked to the serial line 10 by means of a cable 12.

Frequency data was analysed using a multivariate statistical technique implemented on the microcomputer 11.

Batch Milling Experiments 1-6

The batch mill described with reference to Figure 1 was used. The charge used in these experiments was sharp sand. In order to

investigate the widest range of milling conditions experiments were carried out in which the pulp density and volume were altered according to an experimental design. Table 2 shows the initial, intermediate and final conditions for each of the experiments.

5 For example, in experiment 1, the mill was filled to the 120% level (100% full is defined as completely filling the voids between the balls) with a sharp-sand/water mixture (sand 40% by volume). As the milling progressed the mill was stopped at 5 minute intervals and a measured volume of pulp was removed from the mill. This effectively reduced the volume while not affecting the density. On reaching a pulp volume of 90%, aliquots of water were added to the mill, with the effect of increasing the pulp volume and reducing the pulp density (eventually to 119% & 25% respectively). The experiment was concluded with the addition of unground sharp sand to 15 the mill, to introduce a bimodal distribution in the particle size, and the contents were milled for a further 35 minutes (final pulp volume and density were 92% & 40% respectively). In the 6th experiment only very small samples of pulp were removed so that the pulp density and volume were held effectively constant. This 20 experiment was designed to study the effects of particle size only. Milling conditions in experiment 6 (in terms of ball charge and mill rotation speed) were different to the conditions in experiments 1 to 5. For this reason the results of experiment 6 were not used as part of the 'PLS model training set' described later.

25 The samples of slurry removed from the mill were used to estimate the particle size distribution and pulp density. Particle size measurements were made using a combination of sieving, for particle diameters ranging from 125 to 1000 microns, and a Malvern (laser diffraction) sizer for sub-125 micron particles. Percentage 30 undersize by weight was determined for 12 particle diameters (1000, 500, 250, 125, 87.2, 53.5, 28.1, 16.7, 10.1, 6.2, 3.8 and 1.9 microns).

Analysis of Acoustic Signals

35 The relationships between the acoustic emission frequency

distribution to the particle size distribution, pulp density and volume were explored using two multi-variate statistical techniques: principal components analysis and partial least squares modelling (PC and PLS).

5

Effect of particle size distribution

The particle size distribution in the mill mainly influences the overall amplitude of the acoustic emission. As the particle size is reduced the acoustic emission increases in amplitude. This increase is more pronounced in the higher frequency bands. This is illustrated by the results from experiment 6 in which the pulp volume and density were held constant (Figure 2) and the particle size decreased with time. As comminution progressed acoustic power increased across the whole of the frequency range (Figure 3).

15 The peak acoustic power remains in band 6 (3.1KHz) throughout the experiment, however the distribution becomes skewed towards higher frequencies (Figure 4).

Audio noise produced by a ball mill appears to be largely due to collisions between the balls and between balls and the mill liner. The presence of mineral particles reduce the impact velocity of the balls, the larger particles having the greater effect.

20

Effect of pulp volume

Changing the volume of material in the mill has two effects on the acoustic frequency distribution. Firstly, as the volume is increased the overall emission intensity decreases. Secondly, the acoustic power shifts to lower frequencies.

The results obtained from experiment 1 illustrate these trends. In the first stage of the experiment (0-50 min) the pulp volume was changed from 120% to 80% (Figure 5).

30

As the pulp volume was reduced the amplitude of the acoustic spectrum increased rapidly (Figure 6). This is due to a combination of comminution of the sand (particularly fast, in terms of particle diameter, in the early stages of milling) and the reduced damping effect as pulp is removed from the mill. At 120% capacity, the peak

35

power is in band 10 (1.25 KHz). As the pulp volume is decreased the peak power shifts to higher frequencies. At 100% full, peak power was in band 6 (3.15KHz). Reducing the pulp volume below 100% increases only the amplitude of the emissions and has no further effect on the peak power frequency (Figure 7).

Effect of pulp density

Increases in the pulp density cause the amplitude of the acoustic spectrum to decrease but have a less pronounced effect on the frequency distribution. The relationship is complex. This is further complicated by the fact that pulp density changes are accompanied by changes in volume and progressive comminution.

These effects are shown in Figures 8 and 9. Between 40 and 70 minutes the pulp density was reduced from 50% to 36% by adding, at five minute intervals, aliquots of water, thereby increasing the pulp volume from 92% to 118%. The reduction in acoustic emission power which normally accompanies decreasing volume in the mill (compare Figure 9 & 6) is, in this case, opposed by the effects of a decreasing pulp density. Therefore one may conclude that lowering the pulp density increases the acoustic emission amplitude.

Quantitative correlation of acoustic signal mill variables

Principal components analysis was used to investigate the multivariate acoustic emission data. Sixteen acoustic features were selected, where features 1 to 15 corresponded to the power in each of the 3rd octave bands shown in Table 1. The 16th feature was a combination of the remaining 8 (312 to 498Hz) third octaves. Figure 10 shows how the acoustic data collected from batch experiments 1 to 5 was distributed. The numbers represent individual power spectra obtained at different times during the batch experiment. Principal component (PC) 1, which accounts for most of the variance in the data, is a measure of the amplitude of the acoustic emission. PC 2 is a measure of the mean frequency of the signal. The change in direction at the top of the plot corresponds to a reverse in frequency shift direction and is associated with lower acoustic power conditions. This suggests that for quantitative analysis,

220

0

ideally, two models should be used to cover the full range of mill operating conditions.

PLS modelling and validation of results

5 The data obtained from these experiments were analysed by PLS. A model was developed to relate the 16 variables in the acoustic data set to the 14 variables in the milling data set (12 particle diameters, pulp volume and pulp density). A total of 78 samples was used to build the PLS model which included the bimodal distribution data acquired in the latter stages of each experiment. A further 10 samples (randomly sampled from batch experiments 1 to 8), none of which had been used in the model building stage, were selected to validate the performance of the model.

10 A comparison of the PLS predictions of the pulp volume, pulp density and the measured particle size distribution are shown graphically in Figures 11-13. Figures 11 and 12 shown ten particle size distributions for particle diameters ranging from 250 to 1.9 microns. (The joining of the points on these graphs has no mathematical significance and is merely a visual aid). The PLS predictions for the particle size distributions compare well with those obtained by sieving and laser diffraction. Figure 13 shows the PLS prediction of pulp volume and pulp density compared with those values which have been calculated and measured respectively.

25 Continuous Milling Experiment 7

The batch ball mill of experiments 1-6 was replaced by a continuous feed 0.6 m diameter x 1.0 m length mill. The grinding medium was a mixture of steel balls ranging in size from 23 to 70 mm. A quartz ore was selected for study.

30 The experimental strategy was similar to that of the batch experiments in that a wide range of milling conditions was investigated, this time by controlling solid feed and water flow rates. Samples of slurry were taken at regular intervals for pulp density and particle size measurement. Acoustic data was sampled continuously during the operation of the mill.

Acoustic data was collected continuously from the ball mill for a period of 15.2 hours. At intervals (typically 20 minutes), samples of the output stream were taken for analysis (total 34). For practical reasons only one particle size diameter (% under 180
 5 microns) and specific gravity were measured for each sample. Changes in milling conditions were effected by altering the feed rate of the mineral and the water flow rate. In these experiments it was assumed that the mill operation acted as a perfect mixer. In
 10 an industrial scale operation it would be necessary to calculate the mill composition from knowledge of the flow rates and particle size distributions of the mill feed and the product, using a suitable grinding simulation package.

Figures 14 and 15 illustrate how particle size and specific gravity changed during milling. In these experiments the mill was
 15 operated over a wide range of conditions to see whether the acoustic spectra were influenced by milling parameters in a similar manner to batch acoustic spectra. As expected, this was indeed the case. For example acoustic spectra show similar trends in amplitude and frequency to those observed in the batch experiments. The dominant
 20 bands have shifted to lower frequencies (band 11, 1KHz). The second peak (bands 19,20) at 150 Hz was not influenced significantly by the milling conditions and was subsequently found to originate in the gearbox driving the mill.

Principal components analysis of the acoustic data reveals
 25 systematic trends which are very similar to those found in the batch experiments. This indicates that the technique is suitable for monitoring continuous processes.

The results from these experiments show:

- 30 (a) The audio acoustic emission character of a batch or continuous mill is dependant on the particle size distribution, the pulp density and volume.
- (b) The exact physical relationship between the acoustic emission and the milling parameters is complex. An empirical modelling approach (PLS) enables the milling parameters to be estimated
 35 from the acoustic emissions without the need for a physical

model.

- 5 (c) The PLS algorithm is very rapid, being able to compute on a micro-computer the particle size distribution, pulp density and volume in less than a second. The rate determining step is the time required to obtain the acoustic emission frequency distribution, in this case 10 seconds. Thus the whole analysis process can provide results fast enough to generate a control response.
- 10 (d) There is no fundamental difference between the nature of acoustic emission from batch or continuous processes.

TABLE 1

FILTER FREQUENCIES AND OPERATION OF THIRD OCTAVE FILTER

5 The third octave filtering system consists of a bank of band-pass filters, the centre frequencies being arranged so that there are 3 filters in each octave.

The filter centre frequencies (KHz) in each (of 8) octaves are tabulated below.

10	1	10.0	2	7.93700	3	6.29960
	4	5.0	5	3.96850	6	3.14980
	7	2.5	8	1.98425	9	1.57490
	10	1.25	11	0.99212	12	0.78745
15	13	0.625	14	0.49608	15	0.39373
	16	0.3125	17	0.24803	18	0.19786
	19	0.15625	20	0.12402	21	0.09843
	22	0.078125	23	0.06201	24	0.04921

20 The output from each of the band-pass filters is squared and passed into an averager. This averager accumulates the data for a specified averaging time and passes this data to the computer.

D1 and D5 are the initial and final %vol Sand in each experiment (D2-D4 are selected intermediate values) V1 and V5 are the initial and final percentage of 'optimal volume' of material in the mill (V2-V4 are selected intermediate values).

* constant volume and density throughout the experiment - mill rotation speed slower in experiment 6

WHAT ~~THE~~ CLAIM IS:-

1. A non-intrusive method for the determination of the value of a physical property of the material within a mill during the comminution of solid material within the mill characterised by the fact that the method comprises the steps of:
 - 5 (a) detecting the acoustic frequency distribution of milling by means of a sound transducer the output from which is an analogue electrical signal, the intensity of which is proportional to the intensity of sound received by the transducer in the audio frequency range,
 - 10 (b) converting the analogue signal to a digital signal,
 - (c) passing the digital signal through a digital band-pass filter to select at least two frequency bands,
 - (d) averaging the power in each band for a specified period of time, and
 - 15 (e) analysing the acoustic power in the bands by means of a multivariate statistical technique to obtain the value of the property.
2. A method according to claim 1 wherein the sound transducer is a microphone.
- 20 3. A method according to either of the preceding claims wherein the property is the particle size distribution of solid particles, the pulp density being milled or the pulp volume during milling.
4. A method according to any one of the preceding claims wherein the analogue electrical signal is amplified.
- 25 5. A method according to any one of the preceding claims wherein the

analogue electrical signal is passed through a band-pass filter.

6. A method according to claim 5 wherein frequencies above 10KHz are removed.

5 7. A method according to either of claims 5 or 6 wherein frequencies below 50 Hz are removed.

8. A method according to any one of claims 5 to 7 wherein the band-pass filter is capable of selecting from 2 to 24 desired frequency bands.

10 9. A method according to any one of the preceding claims wherein the multivariate statistical technique is the method of principal components analysis.

10. A method according to any one of claims 1 to 8 wherein the multivariate statistical technique is the method of partial least squares.

15 11. A method according to any one of the preceding claims wherein the method is carried out on-line.

20 12. A non-intrusive method for the determination of the value of a physical property of the material within a mill, substantially as herein described with reference to any one of the drawings.
